Ocular Biomarkers of Brain Disease

Outline

The retina as a “window to the brain”

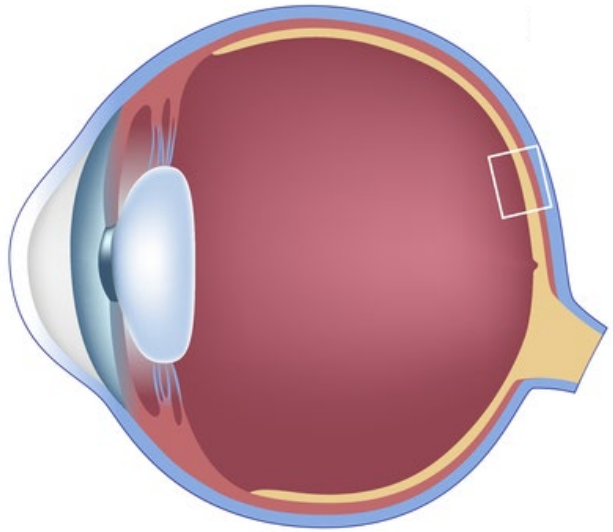
- and a window into brain disease

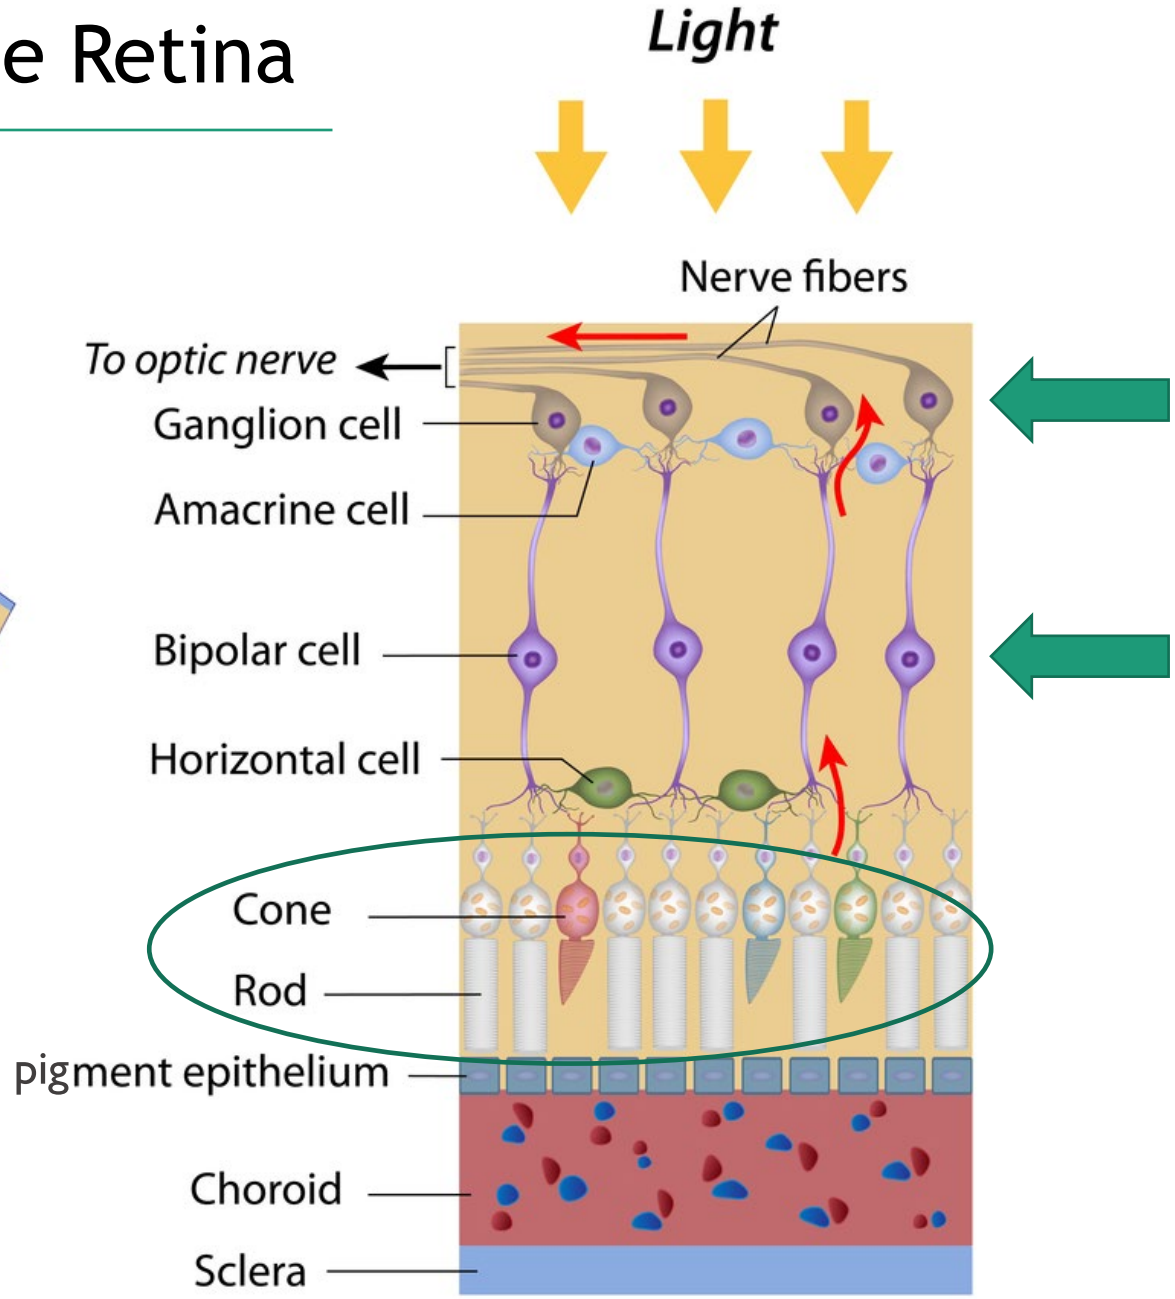
Retinal exam types:

- Imaging of retinal layer thickness
- Imaging of retinal microvasculature
- Electrophysiological recordings of retinal cell activity

Conclusions

Structure of the Retina





The Retina is "A Window to the Brain"

The retina and brain grow out of the same neural tissue during embryonic development

They share important characteristics: neurons, glial cells, layered architecture

They communicate with each other:

- Retinal ganglion cell axons (retinal nerve fiber layer; RNFL) form the optic nerve
- Neurotransmitter input to retina (Ortiz et al., 2017, Doc Ophthalmol)

Changes in the retina often indicate changes in the brain:

- RNFL thinning related to illness progression and cognitive decline in MS, Alzheimer's disease, and schizophrenia (Iseri et al., 2006, J Neuroophthalmology; Toledo et al., 2008 Mult Scler; Liu et al., 2015, BMC Neurol; Lai et al., 2020, Biomarkers in Neuropsychiatry)
- RNFL thinning related to visual hallucinations (Lee et al., 2014, Movement Disorders) and functional decline in PD (Satue et al., 2014, Br. J. Ophthalmology)
- RNFL thinning related to brain volume loss in aging (Ong et al., 2015, Neurosci Letters) and MS (Gordon-Lipkin et al., 2007, Neurology)

Investigators have increasingly turned to studying the retina as a window into brain structure and function. In neuropsychiatric diseases, retinal anatomy as assessed by optical coherence tomography (OCT) and retinal cell function as assessed by various forms of electroretinography (ERG) demonstrate notable changes. In addition, many studies indicate significant correlations between retinal changes and clinical features such as cognitive decline, overall illness severity, and progression of illness. Here, we review retinal findings in psychiatric (schizophrenia, autism, mood disorders, attention deficit hyperactivity disorder, anorexia nervosa), and neurologic (multiple sclerosis, Parkinson's disease, Alzheimer's disease and mild cognitive impairment, Huntington's disease, traumatic brain injury) conditions, in terms of their potential as biomarkers of disease onset, progression, severity, and outcomes. Consistency and variability in findings across studies are highlighted, and implications for future research are discussed. Potential confounds and methodological issues central to studies of retinal structure and function in neuropsychiatry are also considered. The review concludes with discussions of: a) recent advances in retinal imaging and their potential applications for studying brain disorders; and b) the potential for applications of artificial intelligence to increasing the predictive validity of retinal data.

Background: Optical coherence tomography angiography (OCT-A) has emerged as a novel, fast, safe and non-invasive imaging technique of analyzing the retinal and choroidal microvasculature in vivo. OCT-A captures multiple sequential B-scans performed repeatedly over a specific retinal area at high speed, thus enabling the composition of a vascular map with areas of contrast change (high flow zones) and areas of steady contrast (slow or no flow zones). It therefore provides unique insight into the exact retinal or choroidal layer and location at which abnormal blood flow develops. OCTA has evolved into a useful tool for understanding a number of retinal pathologies such as diabetic retinopathy, age-related macular degeneration, central serous chorioretinopathy, vascular occlusions, macular telangiectasia and choroidal neovascular membranes of other causes. OCT-A technology is also increasingly being used in the evaluation of optic disc perfusion and has been suggested as a valuable tool in the early detection of glaucomatous damage and monitoring progression.

OCT-A has been utilized so far to describe abnormalities in multiple sclerosis (MS), Alzheimer's disease, arteritic and non-arteritic optic neuropathy (AION and NAION), Leber's hereditary optic neuropathy (LHON) papilloedema, Parkinson's disease, Huntington's disease, amyotrophic lateral sclerosis (ALS), Wolfram syndrome, migraines, lesions of the visual pathway and cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL). It appears that OCT-A findings correlate quite well with the severity of the aforementioned diseases.

Electroretinography (ERG)

Conditions with ERG Anomalies

- Autism
- Attention deficit-hyperactivity disorder
- Major depressive disorder
- Schizophrenia
- Multiple sclerosis
- Parkinson's disease
- Alzheimer's disease

Conclusions

The retina is a window to the brain, and a window into diseases of the brain

Findings are generally not specific to a single disorder

Findings are likely to represent overall changes in central nervous system function that may be useful in monitoring for disease progression and extent of loss of neural tissue and microvasculature over time

Machine learning approaches to retinal imaging (and/or ERG) data – as opposed to using traditional variables (e.g., layer thickness) may reveal patterns of anatomical changes, or aspects of neural activity, that are especially relevant to clinical prediction and monitoring, and possibly to diagnosis.
